(Received 27 June 2015; published 9 September 2015)

Ferroelectric materials possess a spontaneous electric polarization and may be utilized in various technological applications ranging from nonvolatile memories to solar cells and light polarizers. Recently, hexagonal rare-earth manganites, h - $RMnO_3$ (R is a rare-earth ion), have attracted considerable interest due to their intricate multiferroic properties and improper ferroelectricity characterized by a sizable remnant polarization and high Curie temperature. Here we demonstrate that these compounds can serve as very efficient photovoltaic materials and, in addition, possess remarkable optical anisotropy properties. Using first-principles methods based on density functional theory and considering h - $TbMnO_3$ as a representative manganite, we predict a strong light absorption of this material in the solar spectrum range, resulting in a maximum light-to-electricity energy conversion efficiency of up to 33%. We also predict an extraordinary optical linear dichroism and linear birefringence properties of h - $TbMnO_3$ in a broad range of optical frequencies. These results uncover the unexplored potential of hexagonal rare-earth manganites to serve as photovoltaics in solar cells and as absorptive and birefringent light polarizers.

I. INTRODUCTION

Photovoltaic effects in ferroelectrics have been known for a long time [1]. The photovoltaic effect involves absorption of light, generating electrons and holes due to the photoelectric effect and then separating them to generate a voltage. The photovoltaic effect in ferroelectrics relies on the internal electric field induced by the spontaneous electric polarization in the bulk absorber layer [2]. This internal electric field allows separating the photoexcited charge carriers, eliminating the need for an external bias to produce a potential drop in the interface-limited space-charge region of a conventional semiconductor solar cell [3]. Ferroelectric photovoltaic materials also make it possible to realize above-band gap open-circuit voltage, providing a large photovoltaic efficiency. The latter has been demonstrated using multiferroic perovskite $BiFeO_3$ thin films with structurally controlled steps of the electrostatic potential at nanometer-scale domain walls [4–6].

Another kind of perovskite material—organic halide perovskites, such as $CH_3NH_3PbI_3$ —has recently fostered significant interest due to the improvement of efficiency of solar cells based on these materials up to 20% in last three years, an advance which took matter of decades for other types of solar cells [7,8]. Organic halide perovskites have a long electron-hole diffusion length and low nonradiative recombination rates compared to other thin-film polycrystalline semiconductors [9,10]. In addition, they possess several desirable properties for a photovoltaic material, such as strong optical absorption under light illumination, a direct band gap of appropriate magnitude, small effective masses both for electrons and holes, and benign defect properties [11–14]. There are also indications that organic halide perovskites are ferroelectric, which may be used for efficient separation of electrons and holes [15]. Unfortunately, organic perovskites have limited structural stability, which could hamper outdoor applications.

Inorganic ferroelectric materials (mostly oxide perovskites), on the other hand, often exhibit an electronic band

gap that is too large for an efficient absorber of the solar radiation. For example, the band gap of $BiFeO_3$ is about 2.7 eV, which prevents the absorption in a large part of the visible spectrum. Some other conventional ferroelectric perovskite oxides have band gaps even higher than that of $BiFeO_3$. For example, band gaps of $BaTiO_3$, $PbTiO_3$, and $KNbO_3$ are 3.2, 3.4, and 4 eV, respectively. In fact, earlier efforts to make use of these materials as photovoltaics yielded a very small efficiency due to low optical absorption [16]. More recently, aliovalent doping in $KNbO_3$ [17,18] and modification of the site population or cation ratio in multiferroic Bi_2FeCrO_6 [19] was used to engineer absorption properties of ferroelectric materials and to enhance their light-to-electricity conversion efficiency. In particular, the power conversion efficiency in multilayer multiferroic Bi_2FeCrO_6 solar cells was found to reach 8.1% [19], which is attributed to the low band gap and intrinsic ferroelectricity of the compound.

In this paper, we explore optical properties and a photovoltaic effect in intrinsically narrow-band gap oxide ferroelectric materials—hexagonal rare-earth manganites, h - $RMnO_3$ (R is a rare-earth ion). These materials have recently attracted a lot of excitement due to their improper structural ferroelectricity and coupling to geometrically frustrated spins. The ferroelectric noncentrosymmetric $P6_3cm$ phase of h - $TbMnO_3$ is energetically more favorable than the paraelectric centrosymmetric $P6_3/mmc$ phase [20] in which the polarization originates from the rotation and tilt of the MnO_5 polyhedra and antiphase displacement of Tb and O atoms [21] similar to that found in other h - $RMnO_3$ compounds [22,23]. This mechanism of ferroelectricity is different from that of orthorhombic $TbMnO_3$, where ferroelectricity is induced by spin frustration [24]. At the low temperature, the antiferromagnetic order is mediated by a noncollinear in-plane Mn-O-Mn and collinear Mn-O-R-O-Mn superexchange interactions induced by ferroelectric distortions of the rare-earth ions making these compounds multiferroic [25]. Furthermore, h - $RMnO_3$ materials undergo an isostructural transition with exceptionally large atomic displacements, resulting in an unusually strong magnetoelastic coupling [26]. The broken space

*Corresponding author: tula.paudel@gmail.com

inversion and time reversal symmetries allow a linear magnetoelectric coupling and produce coupled electric and magnetic domains [27,28]. These domains form a unique “cloverleaf” topology pattern with six interlocked structural antiphase and ferroelectric domains merging into a vortex core [29].

The optical properties of the rare-earth manganites appear to be equally exciting from the point of view of light-to-energy conversion as well as production of a polarized light. Their band gaps are of about 1.3 – 1.6 eV, which, according to the well-known Shockley-Queisser criterion, are ideal for utilizing a large part of the visible-light solar radiation for optical excitation [30]. Additionally, these materials have a relatively large remnant ferroelectric polarization with a high Curie temperature that could provide the large intrinsic electric field needed for separating electron-hole pairs. The optical spectroscopy measurements show that these compounds have a sharp absorption edge and have highly anisotropic optical properties [31–33,20].

In rare-earth series, manganites of larger rare-earth ions (La to Dy) crystallize in orthorhombic phase, whereas those of smaller rare-earth ions (Ho to Lu or Y) crystallize in hexagonal phase. Tb and Dy manganites can be epitaxially stabilized in hexagonal phase. Here, we consider hexagonal-TbMnO₃ (*h*-TbMnO₃) as a model system. Similar to other manganites, this material is a charge-transfer insulator with a direct band gap of about 1.4 eV, ideal for photovoltaic applications. In contrast to the bulk orthorhombic phase, *h*-TbMnO₃ shows a relatively large remnant ferroelectric polarization (8 μC/cm²) and a high Curie temperature (>590 K) [21,34]. This sizable remnant polarization is expected to provide the large intrinsic electric field needed for separating electron-hole pairs. High-quality *h*-TbMnO₃ films can be grown on suitable substrates such as Pt(111)/Al₂O₃ (0001) and yttria-stabilized zirconia (YSZ) (111) [34].

We use the first-principles approach (see the First Principles section for details) to study the photovoltaic properties of *h*-TbMnO₃ and compare these properties to those of CdTe, a commercial solar cell absorber, and BaTiO₃, a conventional large-band-gap ferroelectric. We find that *h*-TbMnO₃ has a high absorption coefficient with a particularly sharp onset, due to interband transitions between hybridized Mn 3*d* ground and excited states. This leads to a very high light-to-electricity energy conversion efficiency with a maximum energy conversion efficiency reaching 33%. Furthermore, we demonstrate a remarkable anisotropy in the optical properties of this material, resulting in large linear dichroism and linear birefringence, which allow using *h*-TbMnO₃ as a light polarizer in the visible spectrum range.

II. RESULTS AND DISCUSSION

A. The optical properties and lattice structure

The atomic structure of the hexagonal phase of TbMnO₃ (space group *P*6₃*cm*) is characterized by Mn³⁺ ions surrounded by five O²⁻ ions creating a trigonal bipyramidal environment [Figs. 1(a) and 1(b)]. The layers of MnO₅ bipyramids are interleaved by the planes of Tb³⁺ ions. All Mn³⁺ ions are symmetrically equivalent and occupy the 6*c* Wyckoff position, while the symmetry of Tb³⁺ ions is lower with two of them in 2*a* and the other one in 4*b* Wyckoff

FIG. 1. (Color online) Crystal structure and *d* orbitals splitting for *h*-TbMnO₃. (a) Crystal structure of bulk *h*-TbMnO₃ in space group *P*6₃*cm*. The blue, green and red spheres represent Tb, Mn, and O atoms, respectively. (b) Mn-centered trigonal bipyramid formed of Mn³⁺ and five O²⁻ ions. (c) Schematic representation of the *d* orbitals crystal field splitting under the MnO₅ triangular bipyramid environment. The two doublet states, e'' and e' , are occupied and form the valence band (VB), whereas the singlet a'_1 is unoccupied and forms the conduction band (CB).

position. Oxygen is bonded with Tb and Mn and occupies 2*a*, 6*c*, and 4*b* Wyckoff’s positions. Under the *P*6₃*cm* trigonal symmetry the Mn 3*d* orbitals are split into two doublets, $e'(x^2 - y^2, xy)$ and $e''(yz, zx)$, and one singlet $a'_1(z^2)$ [35]. The orbitals are filled according to the strong Hund’s rule coupling. For the Mn³⁺(3*d*⁴) configuration, both the *xz* and *yz* orbitals, which are directed between the oxygens, and the in-plane *xy* and $x^2 - y^2$ orbitals are singly occupied, whereas the z^2 orbital pointing to the two apical oxygens is empty [Fig. 1(c)]. Therefore, the two doublet e'' and e' states form the valence band while the singlet a'_1 forms the conduction band.

Figure 2 shows the calculated optical absorption spectra of *h*-TbMnO₃ in comparison with those of CdTe, the most common solar cell absorber, and BaTiO₃, a prototypical ferroelectric with a large band gap. It is seen from the figure that the optical absorption of *h*-TbMnO₃ exhibits strong anisotropy with respect to the relative orientation of the polarization of light and the crystal lattice. This polarization anisotropy results from anisotropy of the *h*-TbMnO₃ dielectric tensor $\varepsilon(\omega)$ (see Fig. 3). For hexagonal crystals, such as *h*-TbMnO₃, the dielectric tensor is nondiagonal, i.e., $\varepsilon_{xx} = \varepsilon_{yy} \neq \varepsilon_{zz}$. We denote the two different components of the dielectric tensor using the orientation of the electric field relative to the optical axis [37]. The dielectric component for $e \perp c$ is $\varepsilon_{\perp} = \varepsilon_{xx} = \varepsilon_{yy}$ and that for $e \parallel c$ is $\varepsilon_{\parallel} = \varepsilon_{zz}$, so we label the optical absorption coefficient for the light polarization in the *ab* plane as α_{\perp} and along the *c* axis as α_{\parallel} . An especially strong difference between α_{\perp} and α_{\parallel} is seen in the energy window 1.5 eV < *E* < 2 eV, where $\alpha_{\perp} > \alpha_{\parallel}$ (Fig. 2). In contrast to the hexagonal TbMnO₃, CdTe is cubic and thus the three components of its dielectric tensor are equal, i.e., $\varepsilon_{xx} = \varepsilon_{yy} = \varepsilon_{zz}$. BaTiO₃ is tetragonal at room temperature, but the tetragonal distortion is small, so that the optical absorption spectrum is also nearly isotropic.

FIG. 2. (Color online) Optical absorption spectra. Solid lines of different color represent the calculated results for h -TbMnO₃ (red line for polarization of light in the ab plane and green line for polarization of light out-of-plane along the c axis), CdTe (black line) and BaTiO₃ (blue line). The standard AM1.5G solar spectrum [36] is shown on bottom as a reference with different colors from red to purple indicating the visible light spectrum.

The pronounced asymmetry in the optical absorption of h -TbMnO₃ between polarizations of light along the c axis and in the ab plane leads to a strong linear dichroism for this material in the visible spectral region. Figure 4 shows the calculated linear dichroism $\Delta k = k_{\perp} - k_{\parallel}$ (red curve), along with the linear birefringence $\Delta n = n_{\perp} - n_{\parallel}$ (blue curve). Large positive values of Δk for photon energy less than 2.8 eV (except a narrow region around 2.5 eV) reflect a strong anisotropy of the absorption coefficient ($\alpha_{\perp} > \alpha_{\parallel}$) in this energy range. The linear dichroism changes sign at about $E = 3$ eV. A sizable birefringence is indicative of a refractive index that depends on the polarization and propagation direction of light. Both linear dichroism and linear birefringence can be

FIG. 3. (Color online) The calculated real (red curve) and imaginary (black curve) dielectric spectra ϵ_{\perp} (a) and ϵ_{\parallel} (b).

FIG. 4. (Color online) Anisotropic optical properties h -TbMnO₃. Linear dichroism $\Delta k = k_{\perp} - k_{\parallel}$ (red line) and linear birefringence $\Delta n = n_{\perp} - n_{\parallel}$ (blue line).

exploited for making light polarizers and optical filters. Thus h -TbMnO₃ single crystals can be used both for absorptive and birefringent polarizers of light in the visible spectrum range.

A particularly important characteristic for efficient photovoltaic materials is a sharp absorption edge and a large magnitude of optical absorption. As seen from Fig. 2, this is the case for h -TbMnO₃, whose optical absorption (α_{\perp}) exhibits a remarkably sharp onset at photon energy of 1.4 eV equal to the experimental band gap of h -TbMnO₃ and maintains a large magnitude ($\sim 10^5$ cm⁻¹) throughout the visible frequency range. We find that α_{\perp} for h -TbMnO₃ is about 2 times larger than α for CdTe at photon energy $E < 3.0$ eV (except for a narrow energy window near 2.5 eV) and much larger than α for BaTiO₃ being transparent in the whole visible spectrum range ($E < 3.2$ eV). The other notable features of the α_{\perp} spectrum for h -TbMnO₃ include a plateau of large magnitude (10^5 cm⁻¹) in range of photon energies 1.6 eV $< E < 2.3$ eV, an absorption dip at $E = 2.5$ eV, and a prominent peak at $E = 2.7$ eV. Even though the absorption coefficient is somewhat reduced at $E \sim 2.5$ eV and $E > 2.7$ eV, the absolute value still remains sizable ($> 10^4$ cm⁻¹).

B. Electronic structure of h -TbMnO₃

These features of the absorption spectra can be understood by analyzing the electronic band structure of h -TbMnO₃. Figure 5 shows the calculated band structure along the high-symmetry directions of the h -TbMnO₃ Brillouin zone at energies around the band gap. Both the valence and conduction bands are composed of the Mn 3d and O 2p states with varying degrees of hybridization. Tb states lie at energies far away from the relevant energy range. The lowest-laying conduction bands consist of the three Mn a'_1 states originating from the same spin orbitals split due to the in-plane and out-of-plane hybridizations (Fig. 6). The highest valence bands are composed of the hybridized Mn e' , Mn e'' , and O 2p states. These relatively nondispersive bands provide a high density of states that may be responsible for a strong optical absorption if the optical transitions are allowed by the dipole selection rules. According to the band structure alone, we expect very

FIG. 5. (Color online) Electronic band structure of h -TbMnO₃. The bands are shown along lines connecting high-symmetry points in the Brillouin zone, A (0,0,1/2), Γ (0,0,0), M (1/2,0,0), K (2/3,1/3,0), H (2/3,1/3,1/2), L (1/2,0,1/2). The inset shows the irreducible part of the first Brillouin zone. Bands are colored according to their orbital character: Mn a'_1 (black), Mn e' (green), Mn e'' (red), and O $2p$ (blue). The lower conduction bands consist of Mn a'_1 orbitals, whereas Mn e' , Mn e'' and O $2p$ orbitals contribute to the valence bands. The upper valence bands are dark green due to Mn e' orbitals slightly intermixed with O $2p$ orbitals. The valence bands around -0.75 eV is purple due to strong hybridization between Mn e'' (red) and O $2p$ (blue) states. Bands at energies below -1 eV are blue showing that they largely consist of the O $2p$ states.

strong optical absorption along the A– Γ , K–H, and L–M directions parallel to the c axis, which are labeled as Δ , P , and U , respectively [Fig. 5, inset].

To determine the allowed optical transitions, we analyze the electric dipole matrix elements along the three high-symmetry lines within the first Brillouin zone. The results are given in Table I. The selection rules for the optical transition matrix

TABLE I. The electric dipole transitions between valence bands (e'' or e') and conduction bands (a'_1) along high-symmetry directions in the irreducible part of the Brillouin zone of h -TbMnO₃ (inset in Fig. 5): Δ (Γ to A, $6mm$ symmetry), P (K to H, $3m$ symmetry), and U (L to M, $2mm$ symmetry). The three components of the dipole moment \mathbf{q} are listed separately. Allowed (forbidden) dipole transitions are indicated by A (F).

elements in conjunction with the band structure in Fig. 5 explain the features in the α_{\perp} and α_{\parallel} absorption spectra shown in Fig. 2.

At lower photon energies, the optical absorption for polarization perpendicular to the c direction (α_{\perp}) is controlled by the $\langle a'_1 | q_x | e' \rangle$ and $\langle a'_1 | q_y | e' \rangle$ dipole matrix elements. As seen from Table I, these transitions are allowed along the Γ –A direction, where we see rather flat e' bands at the top of the valence band and a'_1 bands at the bottom of the conduction band (Fig. 5). These bands are separated by the energy gap of about 1.4 eV, have high density, and are responsible for the onset of the optical absorption α_{\perp} at $E = 1.4$ eV (Fig. 2). With increasing the photon energy the α_{\perp} absorption remains large due to the $\langle a'_1 | q_x | e' \rangle$ and $\langle a'_1 | q_y | e' \rangle$ transitions being allowed across the whole Brillouin zone and available valence and conduction bands over the whole range of photon energies, except for the dip at around $E = 2.5$ eV caused by the splitting of the a'_1 excited states (Fig. 5). The peak at $E = 2.7$ eV is associated with the optical transitions from the upper e' valence bands to the top less dispersive a'_1 conduction band. Contrary to the α_{\perp} absorption, there is no optical absorption for polarization parallel to the c direction (α_{\parallel}) in the range of photon energies 1.4 eV $< E < 2$ eV. This is due to the fact that the dipole transition $\langle a'_1 | q_z | e' \rangle$ responsible for α_{\parallel} absorption is forbidden along the Γ –A line (Table I). The onset of the α_{\parallel} absorption occurs at the higher energies, when moving away from the A point along the A–L line we approach the L point and then the L–M line (Fig. 2), where the $\langle a'_1 | q_z | e' \rangle$ dipole transition is allowed (Table I). The respective conduction bands lie at 2.2 eV and higher energies and provide a continuing increase in the α_{\parallel} absorption with the increasing photon energy.

FIG. 7. (Color online) Calculated maximum photovoltaic energy conversion efficiency for h -TbMnO₃, CdTe, and BaTiO₃ as a function of absorber layer thickness.

C. Photovoltaic energy conversion efficiency of h -TbMnO₃

We calculate the maximum photovoltaic energy conversion efficiency, i.e., the ratio of electrical energy output from the solar cell to input energy from the sun, which is the most commonly used parameter to compare the performance of one solar cell to another. The conventional approach to evaluate the photovoltaic conversion efficiency is the well-known Shockley-Queisser (SQ) method [30]. Within this method, the optical absorption spectrum is assumed to be a step function with onset at the band-gap energy. As a result, the efficiency is just a function of the band gap and hence does not depend on details of the absorption spectrum. The SQ efficiency vs band-gap energy curve peaks at around 1.4 eV, incidentally the band gap of h -TbMnO₃, thereby suggesting that this material could be an efficient solar cell absorber. However, the photovoltaic efficiency depends upon other materials-specific properties, such as details of the absorption spectrum, carrier recombination, and thickness of the absorber layer, which are not included in the SQ

approach. Therefore we use a spectroscopic limited maximum efficiency method to evaluate the photovoltaic energy conversion efficiency [38]. This method employs a thermodynamic approach, taking into account the specific shape of the optical absorption spectrum and the energy dependence of radiative recombination losses (see the Methods section for details).

Figure 7 shows the calculated photovoltaic cell efficiencies for h -TbMnO₃, CdTe, and BaTiO₃ as a function of film thickness L . We see that the efficiency increases with increasing L . At small L , the efficiency is small due to small absorption. At large L , the photon absorption reaches a maximum independent of L and is different for different materials. In particular, for h -TbMnO₃, we find the maximum conversion efficiency to be as large as 33%. For a typical absorber layer thickness of $L = 0.5 \mu\text{m}$, the calculated efficiencies for h -TbMnO₃ are 32%, compared to 27% for CdTe and 2% for BaTiO₃. We also obtain other thickness-dependent solar cell parameters, such as the short-circuit current density J_{sc} , open-circuit voltage V_{oc} , and fill factor (Fig. 8). The experimentally measured $J_{sc} = 26 \text{ mA/cm}^2$ and $V_{oc} = 0.87 \text{ eV}$ in CdTe are close to our calculated theoretical limits for this material: $J_{sc} = 23 \text{ mA/cm}^2$ and $V_{oc} = 1.3 \text{ eV}$ at $0.5 \mu\text{m}$, indicating that our method is reliable [39]. Compared to CdTe, the calculated limits for h -TbMnO₃ are $J_{sc} = 30.9 \text{ mA/cm}^2$ and $V_{oc} = 1.16 \text{ eV}$ at $0.5 \mu\text{m}$, showing that h -TbMnO₃ has the capability to realize a high short-circuit current. We point out that the photovoltaic performance of h -TbMnO₃ is comparable with that of the CH₃NH₃PbX₃-based solar cell, as the experimentally achieved values of J_{sc} and V_{oc} are 22.4 mA/cm^2 and 0.92 eV , respectively, for film thickness of $0.35 \mu\text{m}$ [40]. Hence, due to a proper band gap, a very large absorption coefficient in the visible spectrum range, and a relatively large remnant ferroelectric polarization which might be exploited to separate electron-hole pairs, we predict that h -TbMnO₃ is a very promising material for high-efficiency light-to-electricity conversion in solar cell devices.

FIG. 8. (Color online) The calculated device parameters J_{sc} (a), V_{oc} (b), and fill factor (c) for h -TbMnO₃ (blue) ideal solar cell and CdTe (red) ideal solar cell as a function of absorber layer thickness.

III. CONCLUSION

We envision similar photovoltaic and light-polarization properties in other rare-earth manganites. Manganites with smaller rare-earth ions, such as Ho, Er, Tm, Yb, Lu, or Y, are stable in the hexagonal bulk phase. These compounds have a band gap ranging from about 1.3 to 1.6 eV, ideal for effective absorption of the visible-light solar radiation and photoexcitation. The electronic structure of the valence and conduction bands and the optical transition selection rules are determined by symmetry and therefore are similar to those of h -TbMnO₃. This suggests that the hexagonal rare-earth manganites have a large anisotropic optical absorption with a sharp onset. All these materials are ferroelectric with a large spontaneous polarization and a ferroelectric transition temperature well above room temperature. The presence of an internal electric field driven by ferroelectricity allows an efficient separation of the photoexcited electron-hole pairs, eliminating the need for an external bias in a solar cell. Additionally, alloying of the rare-earth ions in these compounds can be used to tune the required material properties, including the optical absorption and mobility, by modifying the electronic structure of the band edges. The mobility of holes in these compounds is expected to be low due to the nondispersive valance band mainly made of Mn- d orbitals. Furthermore, the carrier conductivity could suffer loss by carrier localization coupled to local deformations. All these materials, however, are stable at high temperatures and are isostructural to common polar transparent conducting oxides, such as ZnO, which not only helps to retain the polarization and the intrinsic electric field, but also offers high-quality growth.

We hope, therefore, that our theoretical predictions will stimulate experimental studies to uncover the unexplored potential of hexagonal rare-earth manganites as photovoltaics in solar cells and as absorptive and birefringent light polarizers.

APPENDIX: METHODS

A. First-principles calculations

We use spin-polarized density functional theory (DFT) calculations based on the generalized gradient approximation (GGA) with Perdew-Burke-Ernzerhof (PBE) potentials, as implemented in Vienna Ab Initio Simulation Package (VASP) [41,42]. We consider h -TbMnO₃ of $P6_3cm$ space group symmetry with experimental lattice constants $a = b = 6.27 \text{ \AA}$, $c = 11.46 \text{ \AA}$ and relax the internal co-ordinates with the force convergence limit of 5 meV/atom. The plane-wave

cutoff energy of 525 eV and a $7 \times 7 \times 4$ Monkhorst-Pack k -point mesh centered at the Γ point for total-energy calculation are employed. We treat correlation effects beyond GGA at a semiempirical GGA + U level within a rotationally invariant formalism for the Mn $3d$ orbitals. In order to get reasonable experimental lattice parameters, polarization, and overall electronic structure, we apply $U = 1.5 \text{ eV}$ on the Mn $3d$ orbitals [21]. The calculated band gap of h -TbMnO₃ is 0.84 eV, which is smaller than the experimental band gap of 1.4 eV due to the well-known underestimation of electron-electron correlations within the local density approximation. A collinear antiferromagnetic structure is assumed in the calculations, where the magnetic moments of two Mn atoms in the plane are pointing opposite to the magnetic moment of the third Mn atom in that plane [Figs. 6(a) and 6(c)]. Mn moments within the two Mn planes in the unit cell are opposite, making the net magnetic moment zero [Fig. 6(b)]. This frustrated magnetic order has lower energy compared to a pure A-type antiferromagnetic order [43].

B. Optical properties

The absorption spectra are calculated using the energy-dependent dielectric functions. Within the one-electron picture, the imaginary part of the dielectric function $\epsilon_2(\omega)$ is obtained from the following equation [44]:

$$\epsilon_2(\omega) = \frac{4\pi^2 e^2}{\Omega} \lim_{q \rightarrow 0} \frac{1}{q^2} \times \sum_{c,v,\mathbf{k}} 2w_{\mathbf{k}} \delta(E_c - E_v - \omega) |\langle c | \mathbf{e} \cdot \mathbf{q} | v \rangle|^2. \quad (\text{A1})$$

According to Eq. (A1), $\epsilon_2(\omega)$ is determined by the integrated optical transitions $\langle c | \mathbf{e} \cdot \mathbf{q} | v \rangle$ from the valence states (v) to the conduction states (c), where \mathbf{e} is the polarization direction of the photon and \mathbf{q} is the electron momentum operator. The integration over the \mathbf{k} is performed by summation over special k points with a corresponding weighting factor $w_{\mathbf{k}}$. The real part of the dielectric function $\epsilon_1(\omega)$ is obtained from the imaginary part $\epsilon_2(\omega)$ using the Kramers-Krönig transformation, which is shown in Fig. 3. $\epsilon_1(\omega)$ and $\epsilon_2(\omega)$ are then used to calculate the optical absorption coefficient $\alpha(\omega)$, the refractive index $n(\omega)$, and the extinction coefficient $k(\omega)$ using the following relations [45]:

$$\alpha(\omega) = \sqrt{2} \frac{\omega}{c} \left[\sqrt{\epsilon_1^2(\omega) + \epsilon_2^2(\omega)} - \epsilon_1(\omega) \right]^{1/2}, \quad (\text{A2})$$

$$n(\omega) = \frac{1}{\sqrt{2}} \left[\sqrt{\epsilon_1^2(\omega) + \epsilon_2^2(\omega)} + \epsilon_1(\omega) \right]^{1/2}, \quad (\text{A3})$$

$$k(\omega) = \frac{1}{\sqrt{2}} \left[\sqrt{\epsilon_1^2(\omega) + \epsilon_2^2(\omega)} - \epsilon_1(\omega) \right]^{1/2}. \quad (\text{A4})$$

In the calculations of optical properties, we use the scissor operator Δ , which rigidly shifts the eigenvalues of the conduction bands upward to correct the calculated band gap [46]. A similar approach is used for CdTe (0.79 eV calculated and 1.5 eV experimental band gaps) and BaTiO₃ (2.45 eV calculated and 3.2 eV experimental band gaps), which we employ as benchmarks for optical and photovoltaic properties.

C. Photovoltaic properties

A photovoltaic cell can be approximated by an equivalent ideal diode illuminated under the incident photon flux I_{sun} . When a load resistor is connected to an illuminated photovoltaic cell, the total current can be calculated as follows [47]:

$$J = J_{sc} - J_D = J_{sc} - J_0(e^{qV/kT} - 1). \quad (\text{A5})$$

Here, the first term J_{sc} is the short-circuit current density driven by optical generation, which is given by $J_{sc} = e \int_0^\infty a(E)I_{\text{sun}}(E)dE$, where $I_{\text{sun}}(E)$ is the solar radiation flux and $a(E)$ is the photon absorptivity [Fig. 8(a)]. The absorptivity is given by $a(E) = 1 - e^{-2\alpha(E)L}$ and depends on the absorption coefficient $a(E)$ and absorber thickness L . For h -TbMnO₃, we assume that the absorption coefficient is given by an average over light polarizations so that $\alpha = (2\alpha_\perp + \alpha_\parallel)/3$. The second term in Eq. (A5), $J_D = J_0(e^{qV/kT} - 1)$, is the dark current density that depends on the electron-hole recombination current density, $J_0 = J_0^{nr} + J_0^r$, involving both the nonradiative J_0^{nr} and radiative J_0^r processes at temperature

T and voltage V . The nonradiative recombination is dominant for indirect-band gap compounds and typically is negligible for direct-band gap compounds. The latter is the case for h -TbMnO₃, where the radiative recombination is the dominating loss mechanism. We calculate the radiative recombination rate using a detailed-balance principle assuming the rates of emission and absorption through cell surfaces to be equal [48]. A current due to the black-body radiation absorption in the dark can be used to estimate the emission current. This current is obtained similar to J_{sc} but using the black-body radiation flux I_{bb} , so that $J_0^r = e \int_0^\infty a(E)I_{bb}(E,T)dE$. Thus by knowing the absorption coefficient we can calculate J_{sc} and J_0 . The open-circuit voltage (V_{oc}) shown in Fig. 8(b) is the voltage when J_{sc} is zero. Finally, the maximum energy conversion efficiency is obtained from $\eta = P_{\text{out}}^{\text{max}}/P_{\text{in}}$. Here P_{in} is the total incident solar power density and $P_{\text{out}}^{\text{max}}$ is the maximum electrical output power density, which can be evaluated by numerically maximizing the formula $P_{\text{out}} = JV = [J_{sc} - J_0(e^{qV/kT} - 1)]V$. The fill factor (FF) is calculated from $FF = P_{\text{out}}^{\text{max}}/J_{sc}V_{oc}$ and shown in Fig. 8(c).
